Project Report No. 463
Managing Ramularia collo-cygni through varietal resistance, seed health and forecasting

by

SJP Oxley and ND Havis

SAC, West Mains Road, Edinburgh EH9 3JG.

This project commenced on 1 August 2007. The work was funded by a contract for £47,017 from the HGCA (Project RD-2006-3306).

HGCA has provided funding for this project but has not conducted the research or written this report. While the authors have worked on the best information available to them, neither HGCA nor the authors shall in any event be liable for any loss, damage or injury howsoever suffered directly or indirectly in relation to the report or the research on which it is based.

1. ABSTRACT

Ramularia leaf spot is a fungal disease of barley caused by *Ramularia collo-cygni*. The disease has become widespread in the north of Europe but it also occurs further south and has become endemic in France. An assessment of seed from harvested grain showed the causal fungus to be present throughout the UK. Levels on seed can vary by season and also by region with the highest levels detected in the north and west of the UK and the lowest levels in the east of England. Winter and spring barley varieties showed different levels of Ramularia leaf spot and on the basis of these observations a varietal resistance rating can be made. No varieties exhibited total resistance. The causal fungus developed inside plants of both resistant and susceptible varieties. This was detected using Polymerase Chain Reaction (PCR) diagnostics which can detect *R. collo-cygni* DNA before symptoms are seen. This phase of the disease (asymptomatic) occurs both in resistant and susceptible varieties and it shows DNA levels of the fungus develop initially in the lower leaves and then in the upper leaves, but symptom expression is most extensive on the upper leaves.

Field trials using seed stocks with different levels of contamination with *R. collo-cygni* show that the level of seed infection can have a part to play in the final level of symptoms seen. This was greatest in the spring barley variety NFC-Tipple where a 50% reduction in visible symptoms was observed by using seed with less than 1pg *R. collo-cygni* DNA. It was not possible to determine the impact of sowing seed where *R. collo-cygni* was absent, since no seed stock was completely free from infection. It is recommended however that seed levels are kept as low as possible in regions where the disease is not endemic (1pg DNA England).

Site had the greatest impact on the disease epidemic with disease severity varying by 78% depending upon the site. The main differentiation between high and low disease pressure sites was leaf wetness in early June. A correlation between leaf wetness events in early June with subsequent symptom expression in July was determined on the basis of this research and this corroborates with results taken from previous trials since 2005. In early June, spring barley crops were at Growth Stages (GS) 25-32 and had yet to reach the optimum timing for fungicide control (at GS49). This new information can therefore be used as a risk forecast to warn growers about the potential risk of disease in time to take preventative action. It provides a big step forward in forecasting the risk of Ramularia leaf spot when used alongside other
factors including variety and seed contamination. It will enable action to be taken to protect crops most at risk with fungicide before symptoms appear.

Extending the spring barley risk forecast to other UK and European regions and extending the risk forecast for winter barley, will be the focus priority of future research. Since seed contamination had a lower impact on symptom expression compared to site, using seed contaminated with *R. collo cygni* is likely to have a low impact on the varietal resistance score, but it is recommended that seed stocks used for Recommended List trials have as low a level of seed contamination as is possible. Understanding the impact of seed treatments to eradicate disease from seed is the focus of new research.
2. SUMMARY

Ramularia leaf spot is a disease of barley which is caused by the fungus *Ramularia collo-cygni*. The aim of this proposal is to understand the relationship between *R. collo-cygni*, varietal resistance and seed infection under field conditions to provide information on current varietal resistance.

These aims are a challenge for a project comprising a single season, but this research provides new information which complements previous HGCA research (Oxley & Havis 2008) and also feeds into a new LINK project on the disease.

2.1 Variety resistance

Varieties vary in their susceptibility to Ramularia leaf spot. Tables I and II show the derived resistance ratings and comments on green leaf area retention based on the information from the 2008 season. No variety shows excellent resistance to Ramularia leaf spot and the winter barley varieties tend to show greater susceptibility than spring barley varieties on the current HGCA Recommended List. All data collected from this research and previous research since 1992 has been supplied to Cereal Evaluation Limited.

2.2 Contamination of seed

Seed samples taken at harvest from the UK were tested for presence of the causal fungus of Ramularia leaf spot (*Ramularia collo-cygni*). The fungus was detected on harvested grain throughout the UK in both 2006 and in 2007 (see Figure I for 2007 distribution). An investigation of the amount present on seed showed *R. collo cygni* levels were greater in 2006 averaging 48.3 pg DNA compared to 2007 where seed levels average 9.9 pg DNA. It is proposed that weather conditions the previous July and August play a part in the level of seed contamination and this can be used as part of the risk forecast. Seed contamination levels were higher in samples from Scotland (32.7 pg DNA) and lowest in England (6.2 pg DNA).

1-9 rating where the higher the number the more resistant the variety
No seed stock used in the field trials was completely free from infection with *R. collo-cygni*. Minimum detection levels for this test were determined by the lowest standard on the calibration curve (0.128 pgrams). All seed samples tested from the 2007 harvest had *R. collo-cygni* levels above the min level. It is recommended that seed used for Recommended List variety trials has as low a level as is possible, since seed contamination can influence the overall level of symptoms observed on a variety. The impact of having a greater level of infection on a particular variety was, however, lower than the impact of site on symptom development. For regions where the disease is not endemic, seed health may be a more important factor to ensure the disease does not spread. The greatest impact of seed contamination was observed on the spring barley variety NFC-Tipple where a 50% reduction in visible symptoms was observed by using seed with less than 1pg *R. collo cygni* DNA. It was not possible to determine the impact of sowing seed where *R. collo cygni* was absent, since no seed stock was completely free from infection. It is recommended that seed levels or *R. collo cygni* DNA contamination are kept as low as possible in regions where the disease is not endemic (1pg DNA England, 5pg DNA north and west UK).
2.3 Impact of weather on symptom development and spore release

Previous research shows a correlation between leaf surface wetness in July with spore dispersal (Havis et al. 2009). This is thought to be important for seed contamination, taking the disease into the next season. The greatest impact on Ramularia symptom expression in this research proved to be the site. Having field trials with high and low levels of disease enabled us to determine the risk factors involved. Although this project comprised a single year’s trialling, linking these results with others from previous research shows a correlation between leaf wetness in June with symptom expression in July in spring barley in Scotland. Analysis of leaf wetness events in the first two weeks of April also correlate to Ramularia leaf spot symptoms in late June in winter barley. These leaf wetness events are not associated with airborne spore dispersal events, therefore this knowledge can be used to help predict the risk of an outbreak of Ramularia leaf spot in time to apply protectant fungicides. Why these weather events impact on disease is not fully understood. One possibility could be related to the rate of movement of fungal mycelia within the plant or alternatively there could be small localised spore release from senescing leaves at the bottom of the crop canopy. However, the exact effect of the weather on the movement of the fungus requires further investigation.

These results have enabled us to improve the risk forecast for Ramularia leaf spot (Table III). This information will be used with other information as part of Scottish Government funded research and a new LINK project titled CORACLE to extend its use throughout the UK. It will also be used to modify the potential spread of the disease using current weather models and future climate change models.

</table>
3. TECHNICAL DETAIL

3.1 Introduction

*Ramularia collo-cygni* has become an established barley disease in the north of Europe. The disease has the capability to spread further south, based on knowledge of the climatic conditions that favour the pathogen. The aim of this proposal is to understand the relationship between *R. collo-cygni*, varietal resistance and seed infection under field conditions to provide information on current varietal resistance.

New research shows seed infection is a key method of spreading the disease within a season and potentially into new areas via seed movement. This research will determine the level of contamination in UK seed stocks in winter and spring barley. It will also look at the importance of seed infection on symptom development in the field.

Barley leaf spots were first reported in the north of Britain in 1996 and have now become a recognised economic problem in northern Europe and New Zealand. Barley leaf spots can cause extensive damage to crops in all UK regions including East Anglia, which is typically a low risk area. Forecasting high and low risk areas or seasons is still in it infancy, but leaf wetness and spore dispersal events have been recognised as important factors in previous research (Oxley & Havis, 2008). This research will determine how these factors can be used to forecast risk in time for growers to take action on crops at greatest risk.

Varieties can also differ in their susceptibility to leaf spots (Oxley *et al.*, 2002). The two key types of leaf spots are known as oxidative stress (abiotic spots) and *Ramularia* leaf spot or RLS (biotic spots). Other factors defined in the report include weather conditions conducive to leaf spot development, differences between fungicides in reducing or increasing the severity of leaf spots and optimum timing of fungicides to reduce the disease. The current research project has measured the yield loss from leaf spots. In 2002, yield loss from leaf spots ranged from 0.25 – 0.8 t/ha and an increase in screenings of 3%. In 2006, yield losses ranged from 0.1 t/ha up to 0.9 t/ha with a loss in screenings of 4%. The high yield loss values were from the
variety Optic and the low yield loss from a resistant variety which does not meet market requirements. The figures show the potential savings which could occur if current malting varieties were replaced by Ramularia resistant varieties which meet market requirements. Research has observed a third type of leaf scorch caused by specific fungicide formulations. Fenpropimorph (e.g. Corbel) can cause rapid leaf death under certain weather conditions, while chlorothalonil (Bravo) helps maintain green leaf area.

The development of a diagnostic test specific to the biotic spot *R. collo-cygni* (Havis *et al.*, 2006), demonstrated the presence of *R collo-cygni* in the seed and monitored progress of the pathogen into developing leaves and up to symptom development at flowering. Symptom expression only occurs however when the crop is stressed. Stress from light, moisture or physiological events such as flowering as well as stress associated with fungicides triggers a change in Ramularia. *R. collo-cygni* produces a toxin in response to this stress which is activated by light. Symptoms then develop in areas of the plant exposed to light and the leaf rapidly dies back leading to loss in yield. The role of the *mlo* gene is not as straightforward as was originally thought. Where the crop is not stressed, the *mlo* gene provides the plant with resistance against *R. collo-cygni*. Under heat or light stress however, the *mlo* gene appears to accelerate symptom development making varieties carrying it more susceptible.

In order to give growers resistant varieties to Ramularia leaf spot and an accurate risk forecast, it is important to understand the role Ramularia leaf spot plays within a plant and what triggers the change from an endophyte, living in the plant without causing any apparent damage, to an aggressive pathogen. Information on seed health will also enable an accurate resistance rating to be developed for current and future HGCA Recommended List varieties with knowledge on how seed contamination impacts on varietal resistance. The development of seed treatments to kill Ramularia in seed will be explored through approaches to the major agrochemical companies.

The critical point in our current state of knowledge about Ramularia leaf spot is that we believe that control requires improved seed health and improved fungicide applications in the short term but will also need varieties with better resistance to Ramularia leaf spot in the medium to long term.
3.2 Materials and methods

3.2.1 Monitoring of R. collo-cygni spores in the environment

A Burkard seven day spore sampler was set up at the three trial sites. These machines sample air from the environment which is drawn through a small aperture and passes over coated Mellinex tape. After seven days the tape is removed and divided into segments which correspond to 24 hour periods. These were then halved lengthways and stored at -20 °C. DNA was extracted from the tape using the method described in Fountaine et al. (2007). Extracted DNA was tested for the presence and quantity of Ramularia DNA using a real time PCR test recently developed in our laboratory (Taylor et al., 2009). An automatic weather recording station was situated next to the spore sampler to provide local meteorological data. Spore movement was compared to disease development in adjacent barley trials. Area under disease progress (AUDPC) values from untreated plots were calculated using the trapezoidal rule.

3.2.2 Seed survey

Seed and harvested grain from different UK regions and from different varieties was obtained from the official seed testing stations and agronomy groups and tested for the presence and amount of Ramularia contamination using the established PCR test. Up to 50 samples were tested. The results will show the current incidence of the disease in the UK including areas thought to be at low risk.

3.2.3 Field trials

Field trials were set up at three geographical sites in 2008. Details of the sites are listed below in Table 1.

The aim of the field trials was to determine the importance of site, varietal resistance, fungicide treatment, seed contamination with R. collo-cygni on the disease epidemic.

3.2.4 Importance of seed contamination: Impact of three varieties with two levels of seed contamination at three sites

Three varieties with different Ramularia resistances were chosen. The varieties Optic and Cocktail are defined as susceptible and the variety Decanter resistant to Ramularia leaf spot. Seed stocks used for the recommended list trials were sown alongside seed of the same variety which had been harvested from untreated plots in 2007. The interaction of variety and seed contamination with foliar fungicides was measured. Fungicides were chosen which were effective against the disease and applied at different timings (see Table 2). Disease development, green leaf area and yield were measured.

These experiments were sited on SAC sites where spore traps and weather stations are situated. The experiments will demonstrate the relative importance of varietal resistance, seed infection, external infection with air borne spores, fungicide activity and stress on symptom development and yield.

Fungicide treatments for the spring barley trials are described in Table 2. Previous research showed that the later fungicide treatments gave the best disease control. The untreated control (Treatment 1) was compared to the early fungicide treatment (Treatment 2) to determine the yield and disease impact of the early fungicide. Treatments 3 and 4 comprised the same fungicides used either at the optimum (GS49) timing or sub-optimum timing (GS37). In both these treatments, the same fungicides were applied to the upper leaves.

### 3.2.5 Importance of variety and fungicide on R. collo-cygni and R. leaf spot

The spring barley varieties used in the trials were selected to cover a spread of disease susceptibility to Ramularia leaf spots. Poker, Decanter and Oxbridge were the most resistant. Prestige, Cocktail and Optic were the most susceptible. Trials were fully randomised in complete blocks with three replicates.

### 3.2.6 Varietal resistance of the Recommended List to R. leaf spot

Seed from a selection of Recommended List varieties for 2008 was obtained from Cereal Evaluation Limited (CEL) and tested for Ramularia DNA. Small disease observation plots were sown at 4 sites in Scotland using the two stocks of seed. Observations on Ramularia leaf spot and green leaf area were assessed. Seed contamination levels greater than 5 pg were defined as high, and levels below 5pg DNA were defined as low. No seed stock was completely free from the disease.
3.2.7 Monitoring R. collo-cygni movement within the plant

Three spring barley varieties with differing susceptibility to *R. collo-cygni* were sown in small hill plots at the Lanark trial site in Central Scotland in 2008. The varieties used were the same as those used for the yield loss experiments. Cocktail (susceptible), Decanter (resistant) and Optic (susceptible). Ramularia DNA levels were measured in seeds prior to sowing (Cocktail 29.1 picograms (pg), Decanter 20.5 pg and Optic 20.8 pg). Ramularia levels were measured in each leaf layer throughout the growing season. Visual symptoms were also recorded in the leaves. Seed was harvested at the end of the trial and Ramularia DNA quantified. Area under the curve for Ramularia DNA was calculated using the trapezoidal rule. A spore sampler and weather station at the site allowed Ramularia spore movement to be measured and periods of high leaf surface wetness recorded.

3.3 Results

3.3.1 Monitoring of *R. collo-cygni* spores in the environment

![Figure 1](image)

**Figure 1** Changes in Ramularia DNA and daily average leaf surface wetness over a 5 month period at the Lanark site in 2008.

Ramularia spore production peaked in late July at Lanark in 2008 and continued up to early September, when the crop was still to be harvested (Figure 1). Late July was the
same time that symptoms were widespread on the top two leaves of spring barley varieties. These spore peaks coincided with periods of leaf wetness when the % daily average leaf wetness was greater than 70% (Figure 1 diamond symbols).

Leaf surface wetness events in early June did not correspond with detectable spore release events (Figure 1). Leaf wetness events in early June were, however, important regarding the eventual symptom expression in July. Figure 2 shows the correlation between leaf wetness in June with eventual symptom development in July for the Lanark site in 2008.

This result has been added to results collected since 2005 and it can be concluded that leaf wetness periods in early June can be used as part of a risk forecast where an increase in leaf wetness from 1-14 June (growth stage 25-32) correlates to the eventual severity of disease in July. This provides sufficient warning to advise growers to apply a protectant fungicide at GS45-49 to crops at risk from the disease. Applying a fungicide in early June has some impact on final symptom development, but it is insufficient to provide effective control of the upper leaves.

Figure 2 Correlation between total cumulative duration of maximum leaf wetness between 1-14 June (in minutes) and Area under disease progress for Ramularia leaf spot in spring barley (Mean of all varieties assessed in each year).
A similar correlation for winter barley was seen in 2008 correlating leaf wetness in 1-14 April with Ramularia leaf spot development (Figure 3). More work is required to determine if this correlation is present in previous research.

**Figure 3 Correlation between total cumulative duration of maximum leaf surface wetness between 1-14 April (in minutes) and Area under disease progress for Ramularia leaf spot in winter barley.**

### 3.3.2 Asymptomatic development of *R. collo-cygni* in barley leaf

The qualitative nested PCR test was able to detect the fungus in the barley canopy up to four weeks prior to disease symptoms appearing (Havis *et al*., unpublished). In the same trial at Lanark in 2008 utilising the real time PCR method *R. collo-cygni* was detected in leaf tissue 60 days after sowing (1st July 2008). The build up of *Ramularia* DNA over time was quantified with the fungus reaching ngram/gram leaf levels in leaf layer Flag minus 3 and Flag minus 4 after 90 days. This substantial increase in fungal DNA was not correlated with high symptom severity on the lower leaves, probably due to the low light levels reaching the Flag-2 and Flag-3 leaf layers (data not shown).

Final Ramularia DNA levels in the varieties at the end of the trial were as follows:

\[ y = 21.806x + 4999.6 \]

\[ R^2 = 0.6204 \]
Cocktail - 15.2 pg; Decanter - 60 pg and Optic 15.3 pg (Figure 4). Although there were a number of significant spore release events in July the majority of Ramularia DNA was lower in the canopy indicating that upward movement of fungus is still a contributing factor to final levels in the ear. Future control measures against *R. collo-cygni* may need to be targeted towards protecting the seed while still in the ear and also in preventing the movement of the fungus into the developing plant from infected seed.

**Figure 4** Area under curves for Ramularia DNA at Lanark site. The majority of Ramularia DNA recorded is in the lower leaves.

### 3.3.3 Survey of harvested grain 2006 and 2007

Table 3 shows that seed contamination levels varied from 0.08 pg DNA to 90 pg DNA of *R. collo-cygni*. There were no significant differences between the varieties.

There was a significant difference between the two seasons and seed contamination levels were higher in 2006 compared to 2007 (Table 4 & 5).

Regional differences in DNA levels on harvested grain were also observed. When data was categorised by Scotland (north) and England (south), there were significant differences with greater levels of contamination seen in Scotland.

Splitting the samples by RL region was less successful since so few samples came from the north west. There is, however, a trend towards lower DNA level in the east compared to the north.

If seed is important for the initial spread of Ramularia leaf spot, levels of seed contamination vary significantly by season and also by region. Seed sourced from England, particularly in the east will have lower levels of contamination compared to seed sourced from wetter regions of England or from Scotland.

### 3.3.4 Ramularia collo-cygni contamination of harvested commercial seed

Results from the survey of barley seed taken at harvest in 2006 are sown in Figure 56 and for 2007 in Figure 6.
Figure 5 Ramularia distribution on harvested seed 2006. All green columns had Ramularia levels greater than 0.128 pgrams. Black columns has levels below minimum detection.

Figure 6 Ramularia distribution on harvested seed 2007. All red columns had Ramularia DNA levels above 0.128 pgrams. There were no samples below this threshold in 2007.
The field work occurred over a single season and the relative importance of site, variety, seed contamination and fungicide were determined. The results have been divided to look at these different aspects.

3.3.5 R. collo-cygni contamination of Recommended List seed

Seed stocks used in these experiments were tested for contamination with *Ramularia collo cygni*. Results are reported in Table 6. Levels of contamination less than 5 pg DNA were categorised as low, whilst levels greater than 5 pg DNA were categorised as high. Most seed stocks used in the RL trials were categorised low, but some were as high as 31 pg DNA.

ND – No Data
3.3.6 Importance of variety and seed stock on Ramularia leaf spot

Three spring barley varieties, Cocktail, Decanter and Optic were sown at three different sites in 2008.

Table 7 Seed DNA levels in two seed stocks (pg/100 ng DNA extracted from seed)

<td>4.2</td>
</tr>
</tbody>
</table>

Two seed stocks were used for each variety. The Home saved seed from 2007 was selected from untreated field trials to ensure high seed contamination. The commercial 2008 seed was seed submitted for Recommended List trials. Ramularia DNA was detected in all the seed stocks. Contamination levels (i.e. high and low) were defined on the basis of DNA levels; less than 5pg are low and levels greater than 5pg high.

The 2008 commercial seed has lower levels of DNA compared to the 2007 seed in the case of Optic and Cocktail. The Decanter 2008 seed had higher levels. Since Decanter is a variety used in the north of the UK, it is likely this seed was produced in a region where Ramularia levels are high.

</table>

The area under disease progress curve provides a useful indicator of the overall disease levels through the season (Table 8). Varietal differences were significant and in the order expected with Decanter showing lowest levels of disease and Optic the most. The differences between the seed stocks were not significant suggesting different levels of contamination had no affect on overall symptom expression throughout the time period of this experiment.

The yields were significantly different between the seed stocks and the varieties (Table 11). In all three varieties, the home-saved seed produced lower yields. Decanter, the most resistant variety to Ramularia leaf spot achieved the highest yield out of the three varieties.
The quality of the grain was similar between the varieties and seed stocks (Table 12).

Significant differences were observed between the varieties in green leaf area retention. No differences were observed between the seed stocks.

On the basis of the experiments on these three varieties, varietal choice has a greater impact on disease development than level of contamination with *R. collo-cygni*.

3.3.7 Impact of fungicides and varietal resistance on Ramularia symptoms and yields using six varieties of spring barley

These trials comprised six varieties using one seed stock. Fungicide programmes detailed in the materials and methods are listed below to assist interpretation (Table 14).

Significant differences were observed between the varieties in green leaf area retention. No differences were observed between the seed stocks. On the basis of the experiments on these three varieties, varietal choice has a greater impact on disease development than level of contamination with *R. collo-cygni*.

</tbody>
</table>
The impact of fungicides on Ramularia leaf spot was greater than varietal resistance (Table 15). An early fungicide treatment has some influence on the disease epidemic, but the second treatment applied at GS45 continues to provide the best control. Disease levels on varieties with better resistance (Decanter, Poker and Oxbridge) were lower when compared to the more susceptible varieties (Cocktail, Optic, Prestige). Fungicides were also more effective on the resistant varieties.

A similar pattern of disease control was seen in the single late assessment (Tables 16 and 17) compared to the disease progress results (Table 15). This demonstrates the importance varietal resistance can play in conjunction with fungicides to achieve the best level of control. Timing of fungicide is however important, with the greatest effect seen with the GS4S treatment.

Screenings provide a good measure of quality, particularly from malting barley markets. Although screenings levels were similar in these trials, (Table 19), the best reduction was achieved with the fungicide applied at GS45. This was the same treatment which achieved best control of Ramularia leaf spot.

Green leaf area levels were highest in the optimum fungicide timing for Ramularia leaf spot (Table 20 GS45, treatment 3).

These experiments show that fungicides had a greater impact on Ramularia leaf spot than the variety. There were however differences in the timing of the treatment. There were also interactions between variety and fungicide. Ramularia leaf spot was easier to control on a resistant variety and the overall yield response to disease control was greater on a susceptible variety.
3.3.8 Impact of site on Ramularia symptoms using five varieties

Significance Site <.001
Significance Variety x Site <.001

Levels of disease varied widely at the three sites (Table 21, 22 & 23). Disease levels were low at Perth, but high at Bush and Lanark. There were variety by site interactions however. At a low disease pressure site, Decanter exhibited relatively more disease when compared to Prestige. One reason for this may be the high level of seed contamination on Decanter. Under low disease pressure situations therefore, the importance of seed contamination will increase.

Variety had the greatest impact on late green leaf area (Table 26).

Results from these experiments show site had the greatest influence on Ramularia leaf spot, followed by fungicide treatments and timings and varietal resistance. The impact seed contamination was lower, but no seed stock was fully free from the disease.
3.3.9 Impact of Ramularia on Recommended List varieties

Assessments of Recommended List variety trials were undertaken in July 2008. Table 27 shows the results based on an average of five spring barley sites (Perth, Lanark, Bush, Fife, Borders). Winter barley trials were assessed at four sites in June 2008 (Fife, Bush, Lanark, Perth). Results are shown in Table 28.

Differences in Ramularia leaf spot are not significant but differences in green leaf area are significant. Varieties have been differentiated as having good (0-15%), intermediate (16-20%) and poor (greater than 20%) resistance.
3.3.10 Impact of seed contaminated with R. collo-cygni on Ramularia symptoms on 10 varieties grown at 5 sites

Table 29 shows the *R. collo-cygni* DNA levels on the seed of 10 spring barley varieties. Comments on high and low levels of contamination were based on the threshold of greater than 5pg DNA high and less than 5 pg DNA low.

3.4 Discussion

New information from this research can help to address the two principal aims which were to understand the relevance of seed contamination on varietal resistance and the measures required to clean up seed stocks and produce UK data for risk forecast based on variety, stress factors and accurate variety resistance scores for the HGCA Recommended list.

Different factors which can influence the severity of Ramularia leaf spot in a high disease pressure region are discussed and their relative importance quantified. The relative importance is likely to be different in a region where the disease is not endemic.

3.4.1 Site

Some sites in this project and in field trials in previous research resulted in high levels of disease. Other sites only exhibited low levels of disease. Attempting to determine differences at the sites is therefore an important aim to help determine future risk. Previous research showed that airborne spores occur at the end of the season when symptoms are visible in the field and these airborne spore dispersal events are linked to leaf wetness periods. Since these spore events occur in July when symptoms are already present in the crops it is not possible to use this information to forecast an epidemic. It only confirms that an epidemic has occurred and that there is a high risk that seed will become contaminated with *R. collo-cygni* spores.

Looking earlier in the season and comparing the weather patterns of sites which exhibited high and low levels of disease, this project shows that certain weather patterns in May and June can be used to forecast high risk crops before symptoms appear and in time for preventative fungicide applications to be applied. There is a higher risk of an epidemic occurring where there are a high number of cumulative leaf wetness minutes earlier in the season when the crop is tillering. This can be observed in this research, where the Perth site exhibited low levels of disease compared to the Lanark and Bush site. Other differences were seen between the sites (crop elevation, sowing date etc.) so the evidence from this single season is limited. Looking back at previous research, a similar pattern can be seen with a link between leaf wetness events early in the crop development and later disease epidemic. It is not fully
understanding why early leaf wetness leads to a disease epidemic. It is possible that spores are released as a consequence of the leaf wetness and these spores infect the crop. Reasons why this may not be the case are: 1) early fungicides applied at tillering are not as effective as later applied fungicides in controlling the disease; 2) significant spore dispersal associated with these early leaf wetness events are not evident from spore trap data and 3) _R. collo-cygni_ is already present within leaves in the form of mycelia as a consequence of seed-borne infection so there is already potential inoculum inside the plants regardless of external weather patterns. (It is hypothesised that early leaf wetness events are causing stress to the plants which will eventually lead _R. collo cygni_ to exhibit extensive symptoms.). Although the reason for the link between early leaf wetness and symptom expression is not fully understood, it can be used to differentiate high and low disease risk sites as part of the disease forecast. Understanding the reason for its importance is the focus of new research.

### 3.4.2 Foliar fungicides

The importance of foliar fungicides to control disease has been well recognised. Timing of the treatment is also recognised and a later application at booting (GS45) before visible symptoms appear is the main time to achieve the best yield. Earlier foliar treatments at mid-tillering to first node stage (GS25-31) also has an impact on disease and yield, but this is of minor importance. In high disease pressure situations, particularly where a susceptible variety is sown with a high level of contamination with _R. collo- cygni_ this earlier treatment is likely to have greater importance compared to lower risk situations.

### 3.4.3 Varietal resistance and seed contamination

Variatel resistance is the next major method to manage the disease and differences have been observed in symptom expression in both spring barley and winter barley varieties. The level of varietal resistance in the current Recommended List is not sufficient to manage the disease alone, but in common with other diseases, controlling Ramularia leaf spot on a more resistant variety is more straight forward compared to controlling the disease on a susceptible variety. Susceptible varieties are likely to require higher doses, more applications and more critical timing of application compared to a resistant variety.
One aim of this project was to look at the impact seed infection had on symptom expression. This was important since at some sites, varieties exhibit high levels of disease whilst at others they achieve low levels. Is this difference due to seed infection? This research shows that site has a greater role to play in symptom expression than seed infection. This means that as part of the varietal evaluation system, seed contamination may not play a major part in symptom expression. Looking at some of the more resistant varieties however (e.g. NFC-Tipple), a stock with 0.82 pg DNA exhibited 8.3 % symptoms compared to a stock with 21.1 pg of DNA which averaged 15.8% Ramularia leaf spot. It is recommended that for Recommended List testing, seed stocks are used with as low a level of contamination as can be sourced. The same advice should be given to regions where the disease is not endemic (i.e. east England).

*R. collo cygni* developed asymptotically in resistant and susceptible varieties. Greater levels developed on lower leaves, but no symptoms occurred. This suggests *R. collo cygni* colonises plants via seed and that it can coexist within barley plants without producing symptoms. The stress that triggers necrosis and spotting are not fully understood, but leaf wetness events in early April or June are related to symptom expression. Future research questions are to determine if *R. collo cygni* can be eradicated or if this coexistence can be extended to beyond flowering delaying symptom expression and yield losses.

Since no stocks used in the research were totally free from the disease, it was not possible to compare a seed stock with no seed contamination with one with high levels of contamination. Since the initial source of the pathogen is thought to be the seed, excluding the pathogen from a region must be a major priority and therefore attempting to achieve seed with no viable *R. collo cygni* DNA is seen to be of major importance to reduce the spread of disease into new regions and of high priority. Even in the low risk region of England, the average level of seed contamination was 6.2 pg DNA compared to Scotland where levels averaged 32.7 pg DNA. Seasonal differences in seed contamination were also high. It is suspected that wet weather in July when symptoms are present, is an important weather factor determining the level of seed contamination, despite the fact it is too late to influence the epidemic in the current
season. Our aim should be to reduce contamination through the use of seed treatments to ensure the disease does not become established throughout the UK.

On the basis of this research, a risk forecast can be produced (Table 35) based on the relative importance of factors (Table 32 & Figure 8).
Table 35 Risk forecast for Ramularia leaf spot in spring barley (endemic regions e.g. Scotland)

<table>
<thead>
<tr>
<th>Determining risk</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Leaf wetness:</strong> particularly in early June at the GS25 to GS32 stage. Where leaf wetness events exceed 4000 minutes, crop is at high risk from Ramularia leaf spot</td>
<td>Site has the greatest impact on disease risk and leaf wetness events. Calculating leaf wetness can be done centrally for weather stations, but new research can determine methods to get in-field data</td>
</tr>
<tr>
<td><strong>Variety:</strong> choose variety with greatest level of resistance for specific market</td>
<td>Quality and yield are the main reasons to choose a variety, but longer term aims in plant breeding may make this an important option</td>
</tr>
<tr>
<td><strong>Seed contamination:</strong> choose seed with less than 5pg DNA (Preferably less than 1 pg DNA)</td>
<td>This can be tested and it is recommended seed is tested for <em>Ramularia collo cygni</em></td>
</tr>
<tr>
<td><strong>Seed Treatment:</strong> existing seed treatments are unlikely to affect risk, but if new ones are developed, they should be used to ensure seed contamination is below 1pg DNA</td>
<td>New research is required to investigate methods to control <em>R. collo cygni</em> on seed.</td>
</tr>
<tr>
<td><strong>Fungicides at GS25:</strong> if leaf wetness events are high in May/June and variety is susceptible, ensure GS25-30 fungicide comprises fungicide with effective activity.</td>
<td>Recommended option for high risk crops.</td>
</tr>
<tr>
<td><strong>Fungicides at GS45:</strong> GS45 essential for high risk crops.</td>
<td>Essential option for high risk crops.</td>
</tr>
<tr>
<td><strong>Leaf wetness flowering:</strong> increased risk of seed infection. Home saving seed following extensive leaf wetness event in July (to be quantified) is not recommended in absence of effective seed treatment.</td>
<td>This will help determine the potential risk of seed contamination in the absence of a seed test.</td>
</tr>

Figure 7 Main factors associated with Ramularia risk and management. The factors in wider part of triangle are of greater importance (Percentages in brackets show the best reduction of symptoms for each factor). Value for seed treatment is unknown.
The risk forecast will need to be modified to assist growers in regions where the disease is endemic and also regions where the disease has yet to be found, or where it only occurs sporadically. As with all biological systems, caution is required, since there are unknowns which may impact on the risk. The presence of a second fungal body on barley straw (known as astromella) is not taken account in the risk forecast and its importance is not fully understood. It is possible the leaf wetness periods early in the season are having an impact on the disease.

For UK regions where the disease is not yet established, the relative importance of the risk factors are likely to be different. In these situations, it becomes important to keep potential sources of inoculum out of the system. To address this, the risk forecast can be modified as follows.

**Risk forecast (regions where disease has not been seen) East England**

No routine fungicides are required for Ramularia leaf spot

**Variety:** Choose variety with greatest level of resistance for specific market

**Seed Treatment** – existing seed treatments are unlikely to affect risk, but if new ones are developed, they should be used to ensure seed contamination is below 1pg DNA

**Fungicides at GS25:** Unlikely to be required for Ramularia leaf spot in lower risk region.

**Fungicides at GS45:** Recommended where leaf wetness events were high in May/June and variety is susceptible. More information is required to determine the dates where leaf wetness is correlated to disease in these regions.

</table>
Trial to be yielded

Comments:
Visual and PCR assessments for leaf spots/Ramularia will be done on the trials.

Spore traps trapping Ramularia and Rhynchosporium will be present on the sites
Weather data is being recorded on the sites
There are large scale plots on these sites looking at the spread of Rhynchosporium
and potential seed borne infection of Rhynchosporium

Sample labelling

Label all samples with the study number, date of sampling, plot number and crop
growth stage. Please put the full study number on since this identifies the site and
year.

Study personnel: Study Director, Simon Oxley. Sponsor HGCA
